

# Covariance between relatives: A reminder

Daniel Sorensen\*

April 9, 2023

## 1 Covariance between relatives

The covariance between relatives for a purely additive genetic model with two loci in LD is briefly sketched out. The development involves covariance terms between individuals at the same locus, and covariance terms between individuals at different loci. The term for covariances at the same locus is derived first.

### 1.1 Covariance at a single locus

An example motivates the general case. Imagine a locus denoted  $A$ . The genotype of a father is  $A_1A_2$  and of a mother  $A_3A_4$ . Consider two offspring from these parents, and the possible number of alleles shared identical by descent (IBD) between the two. There are 16 possible genotype combinations for the two offspring genotypes (arranged in a  $4 \times 4$  table, where the columns are the possible genotypes for offspring 1, and the rows the possible genotypes for offspring 2). The number of alleles shared IBD between the two offspring  $i$  and  $j$ ,  $N_{ij}$ , can take the following values

- $N_{ij} = 2$  (4 cases out of 16)
- $N_{ij} = 1$  (8 cases out of 16)
- $N_{ij} = 0$  (4 cases out of 16)

Therefore

$$\begin{aligned} E(N_{ij}) &= 0 \Pr(N_{ij} = 0) + 1 \Pr(N_{ij} = 1) + 2 \Pr(N_{ij} = 2) \\ &= 1 \frac{1}{2} + 2 \frac{1}{4} = 1 \end{aligned}$$

---

\*Center for Quantitative Genetics and Genomics, Aarhus University, C F Møllers Alle 3, bygning 1130, 8000 Aarhus Denmark

and the expected proportion of alleles shared IBD is

$$\frac{E(N_{ij})}{2} = a_{ij} \quad (1)$$

where  $a_{ij}$  is also known as the expected additive genetic relationship between  $i$  and  $j$ , which is the element in the  $i$ th row and  $j$ th column of the additive genetic relationship matrix  $A$ . In the present example the expected proportion is  $a_{ij} = 0.5$ , the expected number is 1, but the two full-sibs can share 0, 1 or 2 alleles IBD, with probabilities 1/4, 1/2 and 1/4, respectively. The expected additive genetic relationship  $a_{ij}$  is also the correlation between the additive genetic values of individuals  $i$  and  $j$ .

Denote the additive genetic value or breeding value of individual  $j$

$$g_j = \alpha z_j$$

where  $\alpha$  is the additive genetic effect for a locus (or additive effect of a gene substitution), and  $z_j$  is the centred genotypic code (centred allele content of the genotype) for the locus. Due to the centring of  $z$

$$E(g_j|\alpha) = \alpha E(z_j) = 0.$$

The additive genetic variance in the population contributed by the locus is

$$V_g = E(g_j^2|\alpha) = \alpha^2 \text{Var}(z_j).$$

Consider the covariance between offspring  $i$  and  $j$ , conditional on  $N_{ij}$ . There are three possible outcomes

- $N_{ij} = 0$ ,

$$\begin{aligned} \text{Cov}(g_i, g_j|N_{ij} = 0) &= E(g_i g_j|N_{ij} = 0) - E(g_i|N_{ij} = 0) E(g_j|N_{ij} = 0) \\ &= E(g_i|N_{ij} = 0) E(g_j|N_{ij} = 0) - E(g_i|N_{ij} = 0) E(g_j|N_{ij} = 0) = 0, \end{aligned}$$

because if individuals do not share alleles IBD, the  $g$ 's are independent.

- $N_{ij} = 1$ ,

$$\text{Cov}(g_i, g_j|N_{ij} = 1) = \frac{1}{2}V_g,$$

the gametic variance.

- $N_{ij} = 2$ ,

$$\text{Cov}(g_i, g_j|N_{ij} = 2) = V_g,$$

the additive genetic variance at the locus. These three cases can be written compactly as

$$\text{Cov}(g_i, g_j|N_{ij}) = \frac{N_{ij}}{2}V_g, \quad N_{ij} = 0, 1, 2.$$

Then, marginally with respect to  $N_{ij}$ ,

$$\begin{aligned}
\text{Cov}(g_i, g_j) &= \text{E}[\text{Cov}(g_i, g_j | N_{ij})] + \text{Cov}[\text{E}(g_i | N_{ij}), \text{E}(g_j | N_{ij})] \\
&= \text{E}[\text{Cov}(g_i, g_j | N_{ij})] \\
&= \frac{\text{E}(N_{ij})}{2} Vg \\
&= a_{ij} Vg
\end{aligned} \tag{2}$$

where the last line uses (1).

### 1.1.1 An alternative derivation

The traditional derivation of the covariance between relatives uses the concept of identity by descent (IBD). Two genes are IBD if they are biochemical replicates produced without mutation from a common ancestral gene. The probability that genes  $A_x$  and  $A_y$  at locus  $A$  are IBD is denoted  $\Pr(A_x = A_y)$ . If genes  $A_x$  and  $A_y$  at locus  $A$  belong in the same individual  $Z$ ,  $\Pr(A_x = A_y) = F_Z$ , the inbreeding coefficient of individual  $Z$ .

The coefficient of parentage between  $i$  and  $j$  is the probability that a gene drawn at random from a particular locus in  $i$  is IBD with a gene drawn at random from the same locus in  $j$ . The probability of drawing a paternal or maternal gene from individual  $i$  (or from individual  $j$ ) is  $1/2$ . Therefore the probability of drawing any of the four possible combinations of maternal or paternal genes from  $i$  and  $j$  is equal to  $1/4$ , the product of these independent events. If the two individuals  $i$  and  $j$  have genotypes at locus  $k$ ,  $A_{ikm}A_{ikp}$  and  $A_{jkm}A_{jkp}$ , where  $m$  and  $p$  stand for the maternally and paternally inherited gametes, then the coefficient of parentage between  $i$  and  $j$  is

$$\begin{aligned}
\Theta_{ij} &= \frac{1}{4}(\Pr(A_{ikm} = A_{jkm}) + \Pr(A_{ikm} = A_{jkp}) + \Pr(A_{ikp} = A_{jkm}) + \Pr(A_{ikp} = A_{jkp})) \\
&= \frac{1}{4}(\Theta_{ikm,jkm} + \Theta_{ikm,jkp} + \Theta_{ikp,jkm} + \Theta_{ikp,jkp}).
\end{aligned} \tag{3}$$

The expected additive genetic relationship  $a_{ij}$  between individuals  $i$  and  $j$  is twice the coefficient of parentage:

$$a_{ij} = 2\Theta_{ij}. \tag{4}$$

New notation is introduced that will be useful for the next section. Let  $z_{ik}^*$  denote the allele content of individual  $i$  at locus  $k$  that can take values  $z_{ik}^* = 0, 1, 2$ . The allele content is the result of independent contributions from the two gametes inherited by  $i$ :

$$z_{ik}^* = z_{ikm}^* + z_{ikp}^*,$$

where each gametic contribution  $z_{ikx}^* = 0, 1$ ,  $x = m, p$ , is a binary random variable with expected value  $\text{E}(z_{ikx}^*) = \Pr(z_{ikx}^* = 1) = p_k$  and variance  $\text{Var}(z_{ikx}^*) = p_k(1 - p_k)$  (not to confuse the expected value  $p_k$  with the subscript  $p$  indicating a gamete from paternal origin). From now on the gametic contributions  $z_{ikx}^*$  are centred, so that  $z_{ikx} = z_{ikx}^* - p_k$ , and therefore  $\text{E}(z_{ikx}) = 0$  and  $\text{Var}(z_{ikx}) = p_k(1 - p_k)$ .

The additive genetic value of individual  $i$  at locus  $k$  is

$$\alpha_k z_{ik} = \alpha_k (z_{ikm} + z_{ikp})$$

and the additive genetic variance contributed by locus  $k$  in the large population maintained by random mating (ensuring that  $z_{ikm}$  and  $z_{ikp}$  are independent) is

$$\text{Var}(\alpha_k z_{ik} | \alpha_k) = \alpha_k^2 2p_k(1 - p_k). \quad (5)$$

Consider two individuals  $i$  and  $j$  with additive genetic values  $\alpha_k z_{ik}$  and  $\alpha_k z_{jk}$ . The covariance between the additive genetic values of  $i$  and  $j$  is

$$\text{Cov}(\alpha_k z_{ik}, \alpha_k z_{jk} | \alpha_k) = \alpha_k^2 \text{Cov}(z_{ik}, z_{jk}). \quad (6)$$

The covariance term is

$$\text{Cov}(z_{ik}, z_{jk}) = \text{Cov}(z_{ikm} + z_{ikp}, z_{jkm} + z_{jkp}). \quad (7)$$

There are four terms contributing to this covariance and in view of the centring each is of the form

$$\text{Cov}(z_{ikm}, z_{jkm}) = \text{E}(z_{ikm} z_{jkm}). \quad (8)$$

Let  $W$  be a binary random variable that takes the value 1 if  $A_{ikx}$  is IBD with  $A_{jxx}$ ,  $x = m, p$ , and 0 otherwise. Then

$$\begin{aligned} \text{E}(z_{ikm} z_{jkm}) &= \text{E}_w(\text{E}(z_{ikm} z_{jkm} | W)) \\ &= \text{E}(z_{ikm} z_{jkm} | W = 1) \text{Pr}(W = 1) + \text{E}(z_{ikm} z_{jkm} | W = 0) \text{Pr}(W = 0) \\ &= \text{E}(z_{ikm} z_{jkm} | W = 1) \text{Pr}(W = 1). \end{aligned} \quad (9)$$

The second term drops out because if  $A_{ikm}$  and  $A_{jkm}$  are not IBD the two alleles are independent,  $\text{E}(z_{ikm} z_{jkm} | W = 0) = \text{E}(z_{ikm} | W = 0) \text{E}(z_{jkm} | W = 0) = \text{E}(z_{ikm}) \text{E}(z_{jkm}) = 0$ . If  $A_{ikm}$  and  $A_{jkm}$  are IBD they are the same allele and  $\text{E}(z_{ikm} z_{jkm} | W = 1) = \text{E}(z_{ikm}^2) = p_k(1 - p_k)$ . On the basis of these results, expression (7) is

$$\text{Cov}(z_{ik}, z_{jk}) = 4\Theta_{ij} p_k(1 - p_k),$$

where  $\Theta_{ij}$  is defined in (3). From (6) the additive genetic covariance between  $i$  and  $j$  is

$$\begin{aligned} \text{Cov}(\alpha_k z_{ik}, \alpha_k z_{jk} | \alpha_k) &= 4\Theta_{ij} \alpha_k^2 p_k(1 - p_k) \\ &= 2a_{ij} \alpha_k^2 p_k(1 - p_k). \end{aligned} \quad (10)$$

The equality in the second line follows from (4).

## 1.2 Covariance involving different loci

Let  $\tilde{\Theta}_{ikm,jlm}$  denote the probability that an allele drawn from locus  $k$  in the maternal gamete of individual  $i$  and an allele drawn from locus  $l$  in the maternal gamete of individual  $j$  are copies of genes that originate from the gamete of a common ancestor. More generally, the property that two alleles from different loci taken from two individuals  $i$  and  $j$  are copies of genes that originate from the gamete of a common ancestor is known as *equivalence by descent*,  $\tilde{\Theta}_{ij}$  (EBD, Weir and Cockerham, 1974).

The centred allele contents of individuals  $i$  and  $j$  at loci  $k$  and  $l$ , respectively are

$$\begin{aligned} z_{ik} &= z_{ikm} + z_{ikp}, \\ z_{jl} &= z_{jlm} + z_{jlp}. \end{aligned}$$

The covariance between  $z_{ik}$  and  $z_{jl}$  is

$$\text{Cov}(z_{ik}, z_{jl}) = \text{Cov}(z_{ikm} + z_{ikp}, z_{jlm} + z_{jlp}). \quad (11)$$

Let the binary random variable  $W$  take the value 1, if a randomly drawn allele from  $i$  at locus  $k$  and an allele from  $j$  at locus  $l$  are EBD. There are 4 terms contributing to (11) that have the following form

$$\begin{aligned} \text{Cov}(z_{ikm}, z_{jlm}) &= \text{E}(z_{ikm} z_{jlm}) \\ &= \text{E}_W[\text{E}(z_{ikm} z_{jlm} | W)] \\ &= \text{E}(z_{ikm} z_{jlm} | W = 1) \text{Pr}(W = 1) + \text{E}(z_{ikm} z_{jlm} | W = 0) \text{Pr}(W = 0) \\ &= D_{kl} \tilde{\Theta}_{ikm,jlm}, \end{aligned} \quad (12)$$

where  $D_{kl}$ , the linkage disequilibrium parameter between loci  $k$  and  $l$  is here the covariance between the maternal allele at locus  $k$  and the maternal allele at locus  $l$  in the gametes of the common ancestor's generation. The equality in the first line holds because terms like  $\text{E}(z_{ikm})$  are equal to zero. The second term in the third line vanishes when  $W = 0$ , because if the alleles are not EBD, they originate from different independent gametes from the common ancestor. Therefore,  $\text{E}(z_{ikm} | W = 0) = \text{E}(z_{ikm}) = 0$  and  $\text{E}(z_{ikm} z_{jlm} | W = 0) = \text{E}(z_{ikm}) \text{E}(z_{jlm}) = 0$ . Summing over all 4 terms yields

$$\begin{aligned} \text{Cov}(z_{ik}, z_{jl}) &= D_{kl} (\tilde{\Theta}_{ikm,jlm} + \tilde{\Theta}_{ikm,jlp} + \tilde{\Theta}_{ikp,jlm} + \tilde{\Theta}_{ikp,jlp}) \\ &= 2\tilde{a}_{ij} D_{kl}, \end{aligned} \quad (13)$$

where  $\tilde{a}_{ij}$  is the expected additive genetic relationship between  $i$  and  $j$ , since

$$\tilde{a}_{ij} = 2\tilde{\Theta}_{ij} = \frac{1}{2} (\tilde{\Theta}_{ikm,jlm} + \tilde{\Theta}_{ikm,jlp} + \tilde{\Theta}_{ikp,jlm} + \tilde{\Theta}_{ikp,jlp}).$$

The covariance between additive genetic values of locus  $k$  of individual  $i$  and locus  $l$  of individual  $j$  is

$$\text{Cov}(\alpha_k z_{ik}, \alpha_l z_{jl} | \alpha_k, \alpha_l) = 2\tilde{a}_{ij} \alpha_k \alpha_l D_{kl}, \quad (14)$$

and the contribution to the covariances between additive genetic values of individuals  $i$  and  $j$  from different loci, including the 8 terms associated with loci  $k$  and  $l$  in  $i$  and loci  $k$  and  $l$  in  $j$  is

$$\alpha_k \alpha_l [\text{Cov}(z_{ik}, z_{jl} | \alpha_k, \alpha_l) + \text{Cov}(z_{il}, z_{jk} | \alpha_k, \alpha_l)] = 4\tilde{a}_{ij} \alpha_k \alpha_l D_{kl}. \quad (15)$$

In (13), (14) and (15)  $\tilde{a}_{ij}$  is used to distinguish it from  $a_{ij}$  in (2). The latter involves the probability of IBD for alleles of the same locus, whereas the former considers the probability of EBD of alleles from different loci. The example below illustrates that the probability of transmission of two alleles drawn from a common ancestor to produce two independent gametes is the same regardless of whether the alleles belong in the same or in different loci. In this case there is no need to use different notation for  $\tilde{a}_{ij}$  and  $a_{ij}$  (see also Lynch and Walsh (1998), page 151).

### 1.2.1 Example

Imagine a sire that at two linked loci  $A$  and  $B$  has genotype  $A_p A_m // B_p B_m$ , where  $m$  and  $p$  stand for the maternal and the paternal haplotype of the sire. Thus, the maternal haplotype carries alleles  $A_m B_m$  and the paternal haplotype  $A_p B_p$ . This sire produces four possible gametes; two non-recombinant types with probabilities

$$\begin{aligned} \Pr(A_p B_p) &= \frac{1}{2}(1 - c), \\ \Pr(A_m B_m) &= \frac{1}{2}(1 - c) \end{aligned}$$

and two recombinant types

$$\begin{aligned} \Pr(A_p B_m) &= \frac{1}{2}c, \\ \Pr(A_m B_p) &= \frac{1}{2}c, \end{aligned}$$

where  $c \in [0, \frac{1}{2}]$  is the probability of recombination between loci  $A$  and  $B$ . The marginal probability of transmission of any of the two alleles at each locus is  $\frac{1}{2}$ .

The sire mates with two randomly chosen females and produces one offspring from each mating, half-sibs  $X$  and  $Y$ .

- Consider locus  $A$  only. Offspring  $X$  inherits genes  $A_p$  or  $A_m$  from its father and genes  $N_p$  or  $N_m$  from its mother. Offspring  $Y$  inherits genes  $A_p$  or  $A_m$  from its father and genes  $M_p$  or  $M_m$  from its mother. Of the 16 possible pair of genes that can be drawn from  $X$  and  $Y$ , in two cases the pair of genes are IBD since they originate from the common father. These cases are the events defined by drawing  $A_p$  from  $X$  and  $A_p$  from  $Y$ , and  $A_m$  from  $X$  and  $A_m$  from  $Y$ . Therefore  $\Theta_{XY} = 1/8$ , since each of the 16 events occurs with equal probability.

- Consider two loci and the event defined by randomly choosing a gene from locus 1 in  $X$  and a gene from locus 2 in  $Y$ . Importantly, these are two independent events. At locus 1,  $X$  can inherit genes  $A_p$  or  $A_m$  from its father and genes  $M_p$  or  $M_m$  from its mother. At locus 2,  $Y$  can inherit genes  $B_p$  or  $B_m$  from its father, and genes  $N_p$  or  $N_m$  from its mother. For these pair of loci this gives rise to 16 possible events each with probability  $1/16$ . In 2 out of the 16 events, the genes drawn from  $X$  and  $Y$  are copies of the haplotype of their common father:  $A_m B_m$  and  $A_p B_p$ . Therefore  $\tilde{\Theta}_{XY} = \Theta_{XY} = 1/8$ . (The same argument holds when instead a gene from locus 2 is drawn from  $X$  and a gene from locus 1 is drawn from  $Y$ . These events occur each with probability  $1/2$ ).

The general result is that when additive genetic relationships are computed tracing related individuals to their most recent common ancestor, the probability of EBD for genes at different loci in different gametes is the same as the probability of IBD for alleles at the same locus (Lynch and Walsh, 1998).

### 1.3 Remarks

The covariance between relatives in multiloci systems is part of a subject of difficult entry. An exact general treatment involving only pairs of loci constitutes a formidable challenge leading to unwieldy expressions, as shown by Weir and Cockerham (1977). The curious reader may wish to glance with awe at formula (6) for the genetic variance in their article, that is almost two pages long! Results assuming lack of inbreeding, epistasis and assortative mating, but accounting for dominance, linkage, and for the dynamics of the linkage disequilibrium parameter over generations, lead to simpler expressions and are given by Weir et al. (1980).
