March 13, 2023

## 1 Covariance between relatives

The covariance between relatives for a purely additive genetic model with two loci in LD is briefly sketched out. The development involves covariance terms between individuals at the same locus, and covariance terms between individuals at different loci. The term for covariances at the same locus is derived first.

## 1.1 Covariance at a single locus

An example motivates the general case. Imagine a locus denoted A. The genotype of a father is  $A_1A_2$  and of a mother  $A_3A_4$ . Consider two offspring from these parents, and the possible number of alleles shared identical by descent (IBD) between the two. There are 16 possible genotype combinations for the two offspring genotypes (arranged in a  $4 \times 4$  table, where the columns are the possible genotypes for offspring 1, and the rows the possible genotypes for offspring 2). The number of alleles shared IBD between the two offspring i and j,  $N_{ij}$ , can take the following values

- $N_{ij} = 2 \ (4 \text{ cases out of } 16)$
- $N_{ij} = 1$  (8 cases out of 16)
- $N_{ij} = 0$  (4 cases out of 16)

Therefore

$$E(N_{ij}) = 0 \Pr(N_{ij} = 0) + 1 \Pr(N_{ij} = 1) + 2 \Pr(N_{ij} = 2)$$
$$= 1\frac{1}{2} + 2\frac{1}{4} = 1$$

<sup>\*</sup>Center for Quantitative Genetics and Genomics, Aarhus University, C F MÃ,lers Alle 3, bygning 1130, 8000 Aarhus Denmark

and the expected proportion of alleles shared IBD is

$$\frac{\mathrm{E}(N_{ij})}{2} = a_{ij} \tag{1}$$

where  $a_{ij}$  is also known as the expected additive genetic relationship between i and j, which is the element in the ith row and jth column of the additive genetic relationship matrix A. In the present example the expected proportion is  $a_{ij} = 0.5$ , the expected number is 1, but the two full-sibs can share 0, 1 or 2 alleles IBD, with probabilities 1/4, 1/2 and 1/4, respectively.

Denote the additive genetic value, or breeding value of individual j

$$g_i = \alpha z_i$$

where  $\alpha$  is the additive genetic effect for a locus (or additive effect of a gene substitution), and  $z_i$  is the centred genotypic code for the locus. Due to the centring of z

$$E(g_j|\alpha) = \alpha E(z_j) = 0.$$

The additive genetic variance in the population contributed by the locus is

$$V_q = \mathrm{E}(g_i^2 | \alpha) = \alpha^2 \mathrm{Var}(z_i).$$

Consider the covariance between offspring i and j, conditional on  $N_{ij}$ . There are three possible outcomes

•  $N_{ij} = 0$ ,

$$Cov(g_i, g_j | N_{ij} = 0) = E(g_i, g_j | N_{ij} = 0) - E(g_i | N_{ij} = 0) E(g_j | N_{ij} = 0)$$
  
=  $E(g_i | N_{ij} = 0) E(g_j | N_{ij} = 0) - E(g_i | N_{ij} = 0) E(g_j | N_{ij} = 0) = 0,$ 

because if individuals do not share alleles IBD, the g's are independent.

•  $N_{ij} = 1$ ,

$$Cov(g_i, g_j | N_{ij} = 1) = \frac{1}{2} V_g,$$

the gametic variance.

•  $N_{ij} = 2$ ,

$$Cov(q_i, q_i|N_{ij}=2)=V_q$$

the additive genetic variance at the locus. These three cases can be written compactly as

$$Cov(g_i, g_j | N_{ij}) = \frac{N_{ij}}{2} Vg, \quad N_{ij} = 0, 1, 2.$$

Then, marginally with respect to  $N_{ij}$ ,

$$Cov(g_i, g_j) = E[Cov(g_i, g_j | N_{ij})] + Cov[E(g_i | N_{ij}) E(g_j | N_{ij})]$$

$$= E[Cov(g_i, g_j | N_{ij})]$$

$$= \frac{E(N_{ij})}{2} Vg$$

$$= a_{ij} Vg$$
(2)

where the last line uses (1).

### 1.2 Covariance involving different loci

Let  $\Theta_{ij}$  denote the coefficient of coancestry, equal to the probability that alleles from two loci k and l in the randomly drawn gametes from individuals i and j, are IBD. Notation  $\tilde{\Theta}_{ij}$  is used to distinguish from the coefficient of coancestry for single loci  $\Theta_{ij}$ . The computation of  $\tilde{\Theta}_{ij}$  involves the rate of recombination between loci k and l and the number of generations back to the common ancestor of individuals i and j.

At locus k, individual i has genotype  $z_{ik}$ , coded as (0,1,2) and at locus l, individual j has genotype  $z_{jl}$ , also originally coded as (0,1,2). Let  $z_{ikm} = 0,1$  and  $z_{ikp} = 0,1$ , be the binary random variables representing the maternal and paternal gametic contributions to  $z_{ik}$  with similar coding for  $z_{jl}$ . Then

$$z_{ik} = z_{ikm} + z_{ikp},$$
  
$$z_{jl} = z_{jlm} + z_{jlp}.$$

Assume that these binary random variables are centred so that  $E(z_{ikm})$ , say, is equal to zero, which renders  $z_{ik}$  and  $z_{jl}$  also centred.

The covariance between  $z_{ik}$  and  $z_{jl}$  is

$$Cov(z_{ik}, z_{il}) = Cov(z_{ikm} + z_{ikp}, z_{ilm} + z_{ilp}).$$

$$(3)$$

Let the binary random variable W take the value 1, if a randomly drawn gamete from i is IBD with a randomly drawn gamete from j, and zero otherwise. Then  $\Pr(W=1) = \tilde{\Theta}_{ij}$ . There are 4 terms contributing to (3) and all have the following form:

$$Cov(z_{ikm}, z_{jlm}) = E(z_{ikm}, z_{jlm}) - E(z_{ikm})E(z_{jlm})$$

$$= E_W[E(z_{ikm}, z_{jlm}|W)]$$

$$= E(z_{ikm}, z_{jlm}|W = 1) \Pr(W = 1) + E(z_{ikm}, z_{jlm}|W = 0) \Pr(W = 0)$$

$$= D_{kl}\tilde{\Theta}_{ij}, \qquad (4)$$

where  $D_{kl}$ , the linkage disequilibrium parameter between loci k and l, is here the covariance between the maternal allele at locus k, and the maternal allele at locus l, and  $\tilde{\Theta}_{ij}$  is the probability that the gametes drawn are IBD. The second term in the third line vanishes

when W = 0, because if the gametes are not IBD, they are independent,  $E(z_{ikm}|W = 0) = E(z_{ikm}) = 0$  and  $E(z_{ikm}, z_{jlm}|W = 0) = E(z_{ikm})E(z_{jlm}) = 0$ . Summing over all 4 terms yields

$$Cov(z_{ik}, z_{jl}) = 4D_{kl}\tilde{\Theta}_{ij}$$

$$= 2\tilde{a}_{ij}D_{kl}, \qquad (5)$$

where  $\tilde{a}_{ij}$  is the expected additive genetic relationship between i and j, since  $\tilde{a}_{ij} = 2\tilde{\Theta}_{ij}$ .

The covariance between additive genetic values of locus k of individual i and locus l of individual j is

$$Cov(\alpha_k z_{ik}, \alpha_l z_{jl} | \alpha_k, \alpha_l) = 2\tilde{a}_{ij} \alpha_k \alpha_l D_{kl}.$$
(6)

In (5) and (6)  $\tilde{a}_{ij}$  is used to distinguish it from  $a_{ij}$  in (2). The latter involves the probability of IBD of alleles at single loci, whereas the former considers the probability of IBD at pairs of alleles in gametes from two loci.

The following argument provides a little insight into the form of  $\tilde{\Theta}_{ij}$ . Let X = 1 if recombination occurs between loci k and l, and 0 otherwise. It is assumed that recombination occurs with probability c. Then

$$\tilde{\Theta}_{ij} = \Pr(\text{alleles from } k \text{ and } l \text{ are IBD}|X=0) \Pr(X=0) + \Pr(\text{alleles from } k \text{ and } l \text{ are IBD}|X=1) \Pr(X=1).$$

A recombination event renders the second term equal to zero, and therefore

$$\tilde{\Theta}_{ij} = \Theta_{ij} \Pr(X = 0). \tag{7}$$

Above,  $\Theta_{ij}$  is the coefficient of coancestry for a single locus model because in the absence of recombination the chromosome segment containing alleles from loci k and l is inherited as a single allele. The term  $\Pr(X=0)$  is of the form  $(1-c)^t$  where t denotes time in generations.

As an example, taken from Lynch and Walsh (1998), consider the expected additive genetic relationship between an individual i and its ancestor j, t generations back, for a pair of loci k and l. The ancestor's generation displays a certain amount of linkage disequilibrium  $D_{kl}$ . From t=0 onwards the ancestor's population is maintained by random mating under conditions where the forces that maintained disequilibria are relaxed. Then the expected additive genetic relationship between an individual i and its ancestor j involving loci k and l is

$$\tilde{a}_{ij} = 2\tilde{\Theta}_{ij} = 2\Theta_{ij}(1-c)^t, \quad t = 0, 1, \dots$$

When t = 0, i and j involve a parent and its offspring,  $\Theta_{ij} = \tilde{\Theta}_{ij} = 1/4$  and  $a_{ij} = \tilde{a}_{ij} = 1/2$ . The term  $D_{kl}$  in (6) is the coefficient of linkage disequilibrium between loci k and l in the ancestor's generation. The coefficient of coancestry  $\tilde{\Theta}_{ij}$  decreases with time t and increases with tight linkage between loci k and l (relatively smaller values of the probability of recombination c).

#### 1.3 Remarks

The covariance between relatives in multiloci systems is part of a subject of difficult entry. An exact general treatment involving only pairs of loci constitutes a formidable challenge leading to unwieldy expressions, as shown by Weir and Cockerham (1977). The curious reader may wish to glance with awe at formula (6) for the genetic variance in their article, that is almost two pages long! Results assuming lack of inbreeding, epistasis and assortative mating, but accounting for dominance, linkage, and for the dynamics of the linkage disequilibrium parameter over generations, lead to simpler expressions and are given by Weir et al. (1980).
